ABSTRACT

Detection of 21 cm HI emission from the Epoch of Reionization (EoR), at redshifts $z > 6$, is limited primarily by foreground emission. We investigate the chromatic signatures of an all-sky foreground model imprinted by an instrumental transfer function. Using the delay spectrum technique, we demonstrate that the foreground signatures that have the largest impact on the HI signal arise from power received far away from the primary field of view. Comparing data from recent Murchison Widefield Array (MWA) observations with simulations separated into components based on type of emission, we identify diffuse emission near the horizon as a significant contributing factor, even on wide antenna spacings. For signals entering through the primary field of view, compact objects dominate the foreground contamination. These two mechanisms imprint a characteristic *pitchfork* signature on the “foreground wedge” in Fourier space. Based on these results, we propose that selective down-weighting of baselines based on length, direction, and time will mitigate a large fraction of foreground contamination in redshifted 21 cm power spectrum analysis.

Keywords: large-scale structure of Universe — methods: statistical — radio continuum: galaxies — radio lines: general — reionization — techniques: interferometric

1. INTRODUCTION

After the CMB epoch, the period in the history of the universe often referred to as the *dark ages*, followed the epoch of reionization (EoR). This was a period of non-

linear growth of density perturbations and astrophysical evolution. Studying the epoch of reionization holds the key to understanding this evolution. Direct observation of redshifted 21 cm spin flip transition of HI has been identified as a useful probe of the EoR (Sunyaev & Zeldovich 1972; Scott & Rees 1990; Madau et al. 1997; Tozzi et al. 2000; Iliev et al. 2002) and has recently emerged as a very promising experiment to fill the gaps in our understanding of the universe’s history.

Sensitive instruments such as the Square Kilometer Array (SKA) are required for direct observation and tomography of redshifted HI. Numerous precursors to the SKA such as the Murchison Widefield Array (MWA; Tingay et al. 2013; Bowman et al. 2013; Lonsdale et al. 2009), the Low Frequency Array (LOFAR; van Haarlem et al. 2013), and the Precision Array for Probing the Epoch of Reionization (PAPER; Parsons et al. 2010) have become operational with enough sensitivity for a statistical detection of the EoR HI power spectrum (Thyagarajan et al. 2013; Beardsley et al. 2013; Bowman et al. 2006; Pober et al. 2014).

A key challenge in the statistical detection of power spectrum of the redshifted HI signal arises from the contamination by Galactic and extragalactic foregrounds (see, e.g., Di Matteo et al. 2002; Zaldarriaga et al. 2004; Furlanetto et al. 2006). Morales & Hewitt (2004) show that the inherent isotropy and symmetry of the EoR signal in frequency and spatial wavenumber (k) space make it distinguishable from sources of contamination which are isolated to certain k modes by virtue of their inherent spectral smoothness (Morales et al. 2006; Bowman et al. 2009; Liu & Tegmark 2011; Parsons et al. 2012; Dillon et al. 2013). Considerable effort has been made towards

understanding the k -space behavior of foreground signatures in the observed power spectrum (Thyagarajan et al. 2013; Poher et al. 2013; Morales et al. 2012; Trott et al. 2012; Liu & Tegmark 2011; Datta et al. 2010; Bowman et al. 2009; Liu et al. 2009). A general model of scattering of smooth spectrum foregrounds to higher k -modes by the wide-field response of the instrument, into the so-called ‘wedge’, has emerged that provides a high level explanation for the observed foreground power spectrum. The conservative foreground strategy that has developed alongside this work is to discard k -modes which could be contaminated (*avoidance*). The more aggressive alternative is to subtract a sky model and regain access to modes lost by *avoidance*. In both cases, which parts of the sky are most critical to either *avoid* or *subtract* has remained largely uncertain. Here, we will focus primarily on extending the *avoidance* strategy by identifying foreground components most likely to “leak” from foreground modes to EoR modes and demonstrating a scheme for down-weighting these components.

Foregrounds contaminate the EoR HI power spectrum by either having intrinsic spectral variability, high instrumental chromaticity, or through approximations in power spectrum analysis. Here we use existing catalogs and a high fidelity instrumental model to capture both foreground and instrumental chromaticity. To decouple our findings from possible analysis effects, such as those pointed out by Hazelton et al. (2013), we compute power spectra using the individual baseline-based approach of Poher et al. (2013); Parsons et al. (2014). This approximates the power spectrum as the inverse Fourier transform of the spectra generated by the instrument’s correlator.

Matching real observations from the Murchison Wide-field Array with instrumental simulations of the entire known sky, we examine the signature of the power spectrum of each baseline. We report two important findings: the foregrounds most likely to obfuscate the redshifted 21 cm power spectrum are not caused by emission in the central field of view, but rather by bright objects from near the horizon; and, diffuse Galactic emission plays a larger role than previously thought. We quantify this contamination by separating the simulations into components based on type of foreground emission. Using these we arrive at a new method for minimizing the contribution of bright foregrounds which uses prior knowledge of the sky to down-weight adversely contaminated baselines.

In §2 we introduce the delay spectrum technique, then in §3, we describe the MWA setup, summarize the observing parameters and present the resulting data. Simulations of these observing parameters are described in §4 and analyzed by sky location, and type of emission in §5. In §6, we offer an initial description of a more precise foreground avoidance technique. §7 summarizes our work and findings.

2. DELAY SPECTRUM

Interferometer array data known as *visibilities*, $V_f(\mathbf{\bar{u}}, f)$, represent correlations between time-series of electric fields measured by different antenna pairs with separation vectors $\mathbf{\bar{x}}$ and then Fourier transformed along time axis to obtain a spectrum along frequency (f) axis. Here, $\mathbf{\bar{u}} \equiv \mathbf{\bar{x}}f/c \equiv \mathbf{\bar{x}}/\lambda$, c is the speed of light and λ

is the wavelength. $\mathbf{\bar{u}}$ is related to transverse spatial frequency modes ($\mathbf{\bar{k}}_\perp$) of brightness distribution of the sky as $\mathbf{\bar{k}}_\perp \equiv 2\pi\mathbf{\bar{u}}/D(z)$, where $D(z)$ is the transverse comoving distance at a redshift z . If $I(\mathbf{\bar{l}}, f)$ is the emission at different frequencies on the sky as a function of direction unit vector ($\mathbf{\bar{l}}$) specified as direction cosines, $V_f(\mathbf{\bar{u}}, f)$ represents the Fourier decomposition of $I(\mathbf{\bar{l}}, f)$ attenuated by the antenna’s angular power-pattern $A(\mathbf{\bar{l}}, f)$, into transverse spatial frequency modes. Taking into account the instrumental bandpass weights $W_f(f)$, this relation can be written as:

$$V_f(\mathbf{\bar{u}}, f) = \iint_{\text{sky}} A(\mathbf{\bar{l}}, f) I(\mathbf{\bar{l}}, f) W_f(f) e^{-i2\pi\mathbf{\bar{u}}\cdot\mathbf{\bar{l}}} d^2\mathbf{\bar{l}}. \quad (1)$$

We define the *delay spectrum* $V_\eta(\mathbf{\bar{u}}, \eta)$ to be the inverse Fourier transform of $V_f(\mathbf{\bar{u}}, f)$ along the frequency coordinate:

$$V_\eta(\mathbf{\bar{u}}, \eta) = \int V_f(\mathbf{\bar{u}}, f) W'_f(f) e^{i2\pi\eta f} df, \quad (2)$$

where, $W'_f(f)$ is a frequency window weighting function which can be chosen to control the quality of the delay spectrum (Thyagarajan et al. 2013; Vedantham et al. 2012). η represents the signal delay between antenna pairs:

$$\eta = \frac{\mathbf{\bar{x}} \cdot \mathbf{\bar{l}}}{c} = \frac{\mathbf{\bar{u}} \cdot \mathbf{\bar{l}}}{f}. \quad (3)$$

Note that as the visibility is a fully complex quantity, its Fourier transform is fully Nyquist sampled over positive and negative delays. Negative and positive delay¹⁹ correspond to the two hemispheres of the sky as transected by the antenna spacing vector. In this paper, $\mathbf{\bar{u}}$ and $\mathbf{\bar{x}}$ are assumed to be on a coordinate system aligned with the local east, north (along local meridian) and upward directions at the telescope site. Hence, a perfectly Eastward oriented antenna spacing will observe an object in the Eastern sky at positive delay, and conversely for an object in the Western sky. Similarly, an object in the Northern sky will appear at a positive delay at an antenna spacing oriented Northward.

Since we are studying a redshifted HI spectral line, f is a measure of cosmological distance along the line of sight. Consequently, η is a measure of line of sight spatial frequency mode given by $k_\parallel \approx 2\pi\eta f_{21} H_0 E(z)/(c(1+z)^2)$, where f_{21} is the rest frame frequency of 21 cm spin flip transition of HI, and H_0 and $E(z) \equiv [\Omega_M(1+z)^3 + \Omega_k(1+z)^2 + \Omega_\Lambda]^{1/2}$ are standard terms in cosmology. We use $H_0 = 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$ and assume a flat Λ CDM universe with $\Omega_M = 0.27$ and $\Omega_\Lambda = 0.73$.

Thus, $|V_\eta(\mathbf{\bar{u}}, \eta)|^2$ is directly related to the spatial power spectrum of EoR HI distribution, $|V(\mathbf{\bar{k}}_\perp, k_\parallel)|^2$ (Morales & Hewitt 2004). However, foreground objects also emit in radio frequencies. Due to their spatial and spectral (chromatic) structure, the measured $V_\eta(\mathbf{\bar{u}}, \eta)$ is contaminated by foreground radio objects (Thyagarajan et al. 2013; Trott et al. 2012; Morales et al. 2012; Bowman

¹⁹ The terms delay and lag are used interchangeably in this paper.

et al. 2009). These contaminations have to be characterized precisely in order to reduce their impact on EoR HI power spectrum detection sensitivity.

In summary, $V_\eta(\mathbf{\bar{u}}, \eta)$ is closely related to visibilities, $V_f(\mathbf{\bar{u}}, f)$, the basic data blocks measured by each antenna pair, as seen from equation 2. It captures all the effects of EoR HI signal corruption caused by foregrounds and the instrument. At the same time, it is directly related to the sought power $|V(\mathbf{k}_\perp, k_\parallel)|^2$ in k -modes containing critical information about spatial scales. For our analysis, we use an equivalent quantity, $V_\eta(\mathbf{\bar{x}}, \eta) \equiv V_\eta(\lambda \mathbf{\bar{u}}, \eta)$. For purposes of illustration, we often use a simplified quantity $|V_\eta(|\mathbf{\bar{x}}|, \eta)|$.

Figure 1 illustrates the Fourier space in which the delay (and power) spectra of HI from the EoR are presented in this paper. $|\mathbf{\bar{x}}|$ and k_\perp , denoting spatial scales in the transverse direction, form the x -axis. η and k_\parallel , denoting spatial scales along line of sight form the y -axis. Foreground emission maps to a wedge-shaped region in Fourier space, hereafter referred to as the *foreground wedge*, the boundaries of which are determined by antenna spacing and the light travel time across it. These boundaries are called horizon delay limits and are shown by solid lines. Spectral transfer function of the instrument convolves the *foreground wedge* and stretches it further (unshaded narrow strips bounded by solid and dashed lines) along η -axis. This effect has been quantified in Thyagarajan et al. (2013). The width of this narrow strip is inversely proportional to operating bandwidth. Region of Fourier space excluding the *foreground wedge* and the narrow strips is usually called the *EoR window*. These are shown in light and medium shades. However, the instrument used in our study, namely the MWA, has a passband constructed using coarse channels with a characteristic shape giving rise to periodic gratings thereby resulting in repetitions of the *foreground wedge* at multiples of $0.78 \mu\text{s}$. The underlying cause of this effect will be discussed later in this paper.

In the context of EoR studies in Fourier space, the HI power spectrum from the EoR is expected to decrease rapidly with $|\mathbf{k}|$. Hence, the brightest EoR signal will be observed on the shortest baselines and smallest delays. Thus the region of interest for EoR studies is slightly beyond the horizon delay limits (dashed lines) and inside the first grating on either side ($|\eta| \lesssim 0.78 \mu\text{s}$, dot-dashed lines) caused by the instrument's spectral transfer function. We call this region with medium shade as the *EoR window* in this paper. The MWA EoR collaboration actively uses this as a test region in Fourier space for diagnostics on data quality.

The terms antenna spacing and baseline are synonymous in radio interferometry. The latter term is also used broadly to refer to the antenna pair system in a radio interferometer array. We use these terms interchangeably in this paper.

For geometrical intuition, we restrict the orientation (θ_b , measured anti-clockwise from East) of all baselines to lie in the range $-67.5^\circ \leq \theta_b < 112.5^\circ$. Baselines oriented in the other half-plane measure conjugate visibilities with delays of equal magnitude but of opposite sign and hence are ignored in our analysis.

3. EXAMPLE DATA

Figure 1. Illustration of Fourier space in which delay (and power) spectra of HI signals from the EoR are presented. The x -axis denoted by $|\mathbf{\bar{x}}|$ (antenna spacing in m) or k_\perp (transverse wavenumber in units of $h \text{ Mpc}^{-1}$) are equivalent and represent transverse spatial scales. Similarly, the y -axis denoted by η (delay in s or μs) or equivalently, k_\parallel (line-of-sight wavenumber in units of $h \text{ Mpc}^{-1}$) represents spatial scales along the line of sight. The dark shaded region is often referred to as *foreground wedge* where smooth spectrum foregrounds reside. The boundaries of the *foreground wedge* (solid lines) are given by the light travel time for corresponding antenna spacings and are referred to as horizon delay limits. In principle, region outside the wedge is expected to be relatively free of foreground contamination and is called the *EoR window* (light and medium shades). In practice, this contamination is also high in the narrow unshaded white regions (bound by solid and dashed lines) due to convolution by instrumental transfer function. The width of this narrow region is determined by inverse of operating bandwidth. Due to an undesirable spectral response of the instrument used in this study, namely the MWA, we identify a narrower region of high significance to EoR studies (medium shade) and hereafter refer to it as the *EoR window* in this paper.

3.1. The Murchison Widefield Array (MWA)

The MWA was completed in 2012, and after commissioning, began its EoR observing program in 2013. In its final configuration the MWA is a 128-tile interferometer array capable of observing a 30 MHz band anywhere in the range 80–300 MHz. Each tile is a phased array of 16 dipoles each in the shape of a bow-tie. This yields a primary field of view $\gtrsim 20^\circ$ wide and multiple secondary lobes for the tile. The tile arrangement is a centrally condensed core of $\sim 300 \text{ m}$ — there are many spacings in the range 5–50 m — and a radial density that falls off as the inverse of the radius with the longest baselines at 3 km (Beardsley et al. 2012). Here we focus on antenna spacings $|\mathbf{\bar{x}}| \leq 200 \text{ m}$ (spatial scales relevant to reionization) and a frequency range 170–200 MHz. The center frequency 185 MHz corresponds to a redshift, $z \simeq 6.68$.

The bandpass properties used in this paper are illustrated in Figure 2. The MWA bandpass of width 30.72 MHz is divided coarsely into 24 1.28 MHz chunks (dashed lines connecting solid circles) with each chunk weighted by a digital filter. The coarse channel shape is obtained using a 8-tap polyphase filter bank (PFB)

and a Kaiser window with parameter $\beta = 5$. The band-pass correction (*plus* symbols connected by dotted lines) corrects for the shape of the coarse channels. After this correction, the channels at the edges of these chunks have been flagged (solid lines) because they are known to possibly be contaminated by aliasing at a low level. Any spectral flags, or other known weights constitutes $W_f(f)$ in equation 1.

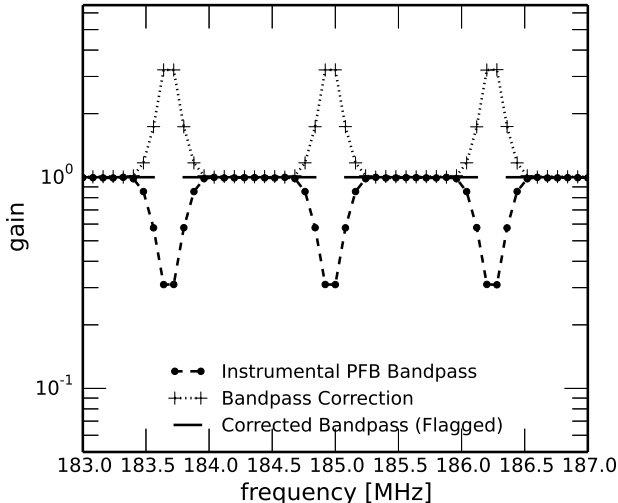

Figure 2. Bandpass properties used in modeling and analysis of delay spectrum of MWA visibilities. The filled circles joined by dotted lines show the 8-tap PFB bandpass shapes obtained using a Kaiser window with parameter $\beta = 5$. The bandpass correction factors applied are shown (*plus* symbols connected by dashed lines). The solid line shows the flagged (gaps) and gain-corrected bandpass shape. These shapes are repeated every 1.28 MHz for the entire bandwidth of 30.72 MHz centered around 185 MHz.

Thermal noise in simulated visibilities is estimated assuming a system temperature of $T_{\text{sys}} = 95$ K per polarization for all frequency channels for all antenna pairs throughout the course of the observation.

3.2. Observation Parameters

The MWA targets two primary low-foreground fields for reionization observations. Here, we focus on the field at RA = 0h, Dec = -30° . The MWA tracks a patch of sky through antenna beams formed and steered electronically by controlling delay settings of an array of dipoles in an MWA tile. These beamformer delay settings can be changed only in discrete steps. The sky is allowed to drift for a certain period of time (usually ~ 30 mins) before the discrete shifts in the beamformer delay settings position the beam to be centered again on the same patch of sky. This process is repeated throughout the course of the observation ≈ 4.86 hours. Figure 3 illustrates how the apparent pointing oscillates around the desired pointing direction.

The observations shown here were observed on Aug 23, 2013. This day has been chosen as a reference data set for comparison within the MWA EoR collaboration and was selected on the basis of low number of known system errors from among a long stretch of stable observing.

Here we have chosen two, 112 second long sections from this night for detailed study. These were chosen to pro-

vide a selection of possible foreground and instrumental conditions. As an example of “nominal” observing setup we choose a zenith pointing; as an example of poor foreground conditions, we choose a pointing when the field is ~ 2 hours from zenith. This pointing has a significantly higher secondary lobe structure and is observed when the bright galactic center is well above the horizon.

The *local sidereal time* (LST) at these two snapshots are shown in Figure 3 as vertical lines at -1.92 hours (i.e., 22.08 hours) and 0.09 hours which are hereafter denoted as *off-zenith* and *zenith* pointings respectively.

Figure 3. MWA tile beam pointing directions during the course of the observation. The x -axis refers to the *local sidereal time* (LST) in hours. The axis on the left refers to longitudes, namely, Right Ascension (RA) and Hour Angle (HA) in degrees. Negative values of RA, HA, and LST are to be interpreted as having been wrapped around by 360° or 24 hours. The axis on the right refers to the declination of the pointing direction. The RA, HA, and declination are plotted with solid, dashed and dotted lines respectively. A “drift and shift” scheme is used. The sky is allowed to drift for ~ 30 mins before the beamformer delay settings change in a discrete step to center the beam around RA = 0h, Dec = -30° . Dot-dashed vertical lines show the LST of *off-zenith* and *zenith* pointings used in our study.

3.3. Initial Data Processing

The data are flagged²⁰ for interference (Offringa et al. 2012, 2010), removing 3% of the data and averaged in time and frequency from the raw 0.5 s, 40 kHz to 2s, 80 kHz. These data are then calibrated to a simulation of the sky containing 2420 point-like objects selected from the MWA Commissioning Survey (MWACS; Hurley-Walker et al. 2014, submitted). MWACS was compiled using observations taken with subsets of the array during the final buildout and commissioning. It has a flux density limit of 25 mJy and a declination range of -12° to -40° evenly covering the field of view of the observations reported here. The objects used in calibration are selected to lie inside the 5% contour of the

²⁰ <http://sourceforge.net/p/aoflagger>

primary lobe of the tile power-pattern. The calibration algorithm – based on a forward modeling software by Sullivan et al. (2012) – computes complex gain solutions per channel per antenna averaged to two minute intervals. The solutions are still fairly low signal-to-noise so we iteratively project along the antenna and frequency dimensions to capture the relatively independent pass-band and antenna-to-antenna variation. First, we average the channel gains over all antennas to obtain a high signal-to-noise measurement of the bandpass. After applying this single passband, we do a second round of calibration and fit second and first order polynomials for amplitude and phase respectively for each antenna. This flattens any residual variation in bandpass and removes small phase slopes due to variation in cable delay. Finally, we fit for an additional phase known to be caused by reflection in 150 m length cables.

3.4. Delay Spectrum after Delay Deconvolution

We obtain the delay spectrum of these calibrated visibilities taking the delay transform of each baseline’s spectrum (equation 2) choosing $W_f'(f)$ to be a *Blackman-Harris* window function. The spectrum is multiplied by the additional weight of the flagged channels which occur rarely for interference and regularly every 1.28 MHz where the edges of coarse channels are known to have a slight aliasing effect. In delay-space, these weights translate into a convolution by a grating point spread function (PSF) with gratings at multiples of $\eta = 0.78 \mu\text{s}$. We deconvolve this PSF using a one dimensional CLEAN algorithm (Taylor et al. 1999) as described for the delay axis by Parsons & Backer (2009); Parsons et al. (2012). The CLEAN procedure iteratively finds and subtracts peak values convolved by the Fourier transform of the weights. We limit the selection of peaks to modes inside the horizon delay limit, corresponding to smooth spectrum objects in the visible sky hemisphere.

In subsequent sections, we plot the amplitude of the delay spectrum, $|V(\bar{x}, \eta)|$, sorted by baseline length, $|\bar{x}|$. Note that visibilities from different baselines have not been averaged together in this analysis.

We show results of delay spectrum from MWA data after deconvolution along delay axis in Figure 4. The principle feature is the *foreground wedge*, whose boundaries, marked by solid white lines, increase linearly with light travel time corresponding to baseline length. Note that the wedge is not filled out uniformly. Each baseline has a different orientation and resulting response to different objects in the sky. It is this variation that we will explore below.

The *off-zenith* pointing has emission notably higher than in the *zenith* pointing inside the *foreground wedge*. This is shown later to be due to response of the array to the bright Galactic center and Galactic plane in the westward sky. Consequently, the contamination into the *EoR window* is also higher. Emission in the *zenith* pointing is more centrally concentrated due to phasing of power-pattern to the zenith, whereas the *off-zenith* pointing has a power-pattern phased eastward of zenith but is also responsive to emission from angles far away from zenith.

Despite delay deconvolution, we still see leakage beyond the cleaned regions indicating the inability of the

Figure 4. Delay spectra of two 112 s Murchison Widefield Array observations of the EoR field at RA = 0h, Dec = -30° at an *off-zenith* pointing (top) when tiles have significant secondary lobes in the direction of the Galactic center and a *zenith* pointing (bottom) where secondary lobes are minimal and the Galaxy has set. To get the delay spectrum, each baseline is Fourier transformed into delay space (y -axis) and the amplitude plotted in order of baseline length (x -axis). For reference, the k -space equivalent of η and $|\bar{x}|$, namely, k_{\parallel} and k_{\perp} are shown at the axes on the right and top respectively. The logarithmic color scale (shown at the right) is common to both panels. White lines mark the boundaries of *foreground wedge* determined by light travel time across each baseline. Smooth spectrum objects predominantly reside in this *foreground wedge*. The various features in this region depend on antenna spacing orientation, secondary lobe structure of the power-pattern, and the sky at that instant.

deconvolution algorithm to fit the measurements perfectly. This is predominant at short antenna spacings where the number of delay modes within the horizon is lesser. This is because the maximum delay envelope (boundary of the wedge) consists of mixed emission from large portions of the sky into a narrow range of delays and the deconvolution algorithm does not have sufficient support in delay space to fit the delay spectrum. However, we wish to emphasize that the purpose of deconvolution is to rid the delay spectra of instrumental artifacts to the best extent possible in order to see the underlying signatures of foreground emission. It is not our intention in this paper to use the deconvolution as a foreground removal tool.

4. SIMULATIONS

We describe power-pattern and foreground models we have used in our simulations.

4.1. Power-pattern

The power-pattern of the MWA tile ($A(\bar{\mathbf{l}}, f)$ in equation 1) is modeled as a mutually-coupled 4-by-4 dipole array with the overall power-pattern of each individual dipole calculated via finite element electromagnetic simulation (Sutinjo et al. 2014). To speed up simulation we find that a phased array of isotropic radiators at a height

of 0.3 m above an infinite ground plane provides a very good approximation to the full simulation, hence we use the idealized dipoles. We also assume that each individual dipole signal has random delay fluctuations of rms 0.05 ns, a number in line with the known repeatability and stability level of the analog signal chain (Bowman et al. 2007).

Figure 5. Models of MWA tile power-pattern in Right Ascension (α) and Declination (δ) coordinates for the *off-zenith* (top) and *zenith* pointings (bottom) at 185 MHz. An MWA tile is modeled as a 4×4 array of isotropic radiators placed 0.3 m above an infinite ground plane. Random fluctuations of rms 0.05 ns have been added to delay corrections during the phased addition of voltages from these isotropic radiators. The logarithmic color scale (shown on the right) is common to both panels.

4.2. Foreground Model

The MWA has a very wide field of view ($\gtrsim 20^\circ$ at 185 MHz) and has non-zero response all the way to the horizon. As already noted, foreground objects fill the *foreground wedge* with an amplitude which depends on the tile power gain in that direction, with objects at the horizon being closest to the boundaries of the *wedge*.

The degree to which these objects leak power into spectral line of sight modes in the *EoR window* will be shown to depend primarily on the brightness of foregrounds near the boundaries of the *foreground wedge*. Thus, it is important to consider an all-sky model for foreground objects in evaluating the features seen in the power spectrum instead of restricting only to the primary field of view.

We use an all-sky foreground emission model that includes both diffuse and bright compact components.

4.2.1. Diffuse Foreground Model

For the diffuse component, we use an all-sky radio foreground model (de Oliveira-Costa et al. 2008) to estimate the emission at 185 MHz. Since this map is predominantly based on the 408 MHz all-sky map of Haslam

et al. (1982) which has an angular resolution of $0.85'$, we smoothed the 185 MHz map to the same resolution. However, to avoid any artifacts from sampling this map, we sample it at $\approx 27'$ intervals. We model the diffuse foreground spectra with a single spectral index at each pixel in the map, found by comparing model maps at 170 MHz and 200 MHz.

A low resolution version of the diffuse foreground model used is shown in Figure 6. Contours of the MWA tile power-pattern shown in Figure 5 are also overlaid. Of notable significance in the *off-zenith* pointing is the presence of a portion of the Galactic plane and the bright Galactic center in the visible hemisphere in the westward sky and the MWA tile's power gain is significantly high ($\gtrsim 12\%$) in that direction. In the *zenith* pointing, the Galactic plane has set and the contour level of power-pattern in that direction is at least 16 times smaller.

Figure 6. Sky brightness temperature (in K) of the diffuse foreground model at 185 MHz in Right Ascension (α) and Declination (δ) coordinates visible during *off-zenith* (top) and *zenith* (bottom) pointings. The color scale on the right is logarithmic and is common to both panels. Contours of power-pattern shown in Figure 5 are overlaid. The contour levels shown are 0.00195, 0.00781, 0.0312, 0.125, and 0.5. The Galactic center and a portion of the Galactic plane are prominently visible during the *off-zenith* pointing and the MWA tile power gain is significant ($\gtrsim 12\%$) in that direction. In contrast, emission from the Galactic plane in *zenith* pointing is significantly lesser.

4.2.2. Compact Foreground Model

We use a combination of NRAO VLA Sky Survey (NVSS; Condon et al. 1998) at 1.4 GHz and Sydney University Molonglo Sky Survey (SUMSS; Bock et al. 1999; Mauch et al. 2003) at 843 MHz to provide our compact object catalog due to their complementary survey footprints covering the entire sky, and matched flux sensitivity and angular resolution. The SUMSS catalog covers the sky with declination $\delta < -30^\circ$ with a limiting peak brightness of 6–10 mJy/beam and an angular resolution of $\sim 45''$. The NVSS covers the sky with $\delta > -40^\circ$ with

a similar angular resolution and a limiting flux density of ≈ 2.5 mJy for compact objects.

From the SUMSS catalog, we select compact objects whose deconvolved major axes are equal to $0''$. From the NVSS catalog, we excluded objects that overlap with those in the SUMSS survey footprint. Compact objects from NVSS were selected if the convolved major axes were not greater than $\approx 47''$, which is almost equal to the angular resolution of the survey. Using a mean spectral index of $\langle \alpha_{\text{sp}} \rangle = -0.83$ (flux density, $S(f) \propto f^{\alpha_{\text{sp}}}$) obtained by Mauch et al. (2003) for both NVSS and SUMSS catalog objects, we calculate the corresponding flux densities at 185 MHz, S_{185} . From this subset, we choose compact objects with $S_{185} \geq 10$ Jy. The selection of such bright compact objects is not affected by minor differences in flux sensitivity of the two surveys. We verified that our selection criteria ensure a similar areal density of objects in the two surveys.

Based on these criteria, we selected 133 objects from the SUMSS catalog and 336 objects from the NVSS catalog. Together with the diffuse foreground model, we obtain an all-sky foreground model consisting of both compact and diffuse emission.

Figure 7. Flux densities (in Jy) of bright compact objects at 185 MHz in Right Ascension (α) and Declination (δ) coordinates visible during *off-zenith* (top) and *zenith* (bottom) pointings. The color scale on the right is logarithmic and is common to both panels and corresponds to the color-coded filled circles. Contours of power-pattern shown in Figure 5 are overlaid. The contour levels shown are 0.001953125, 0.0078125, 0.03125, 0.125, and 0.5. The locations of bright compact objects appear to be random.

4.3. Comparison with Data

With the aforementioned all-sky foreground model, and instrumental and observational parameters, we simulate visibilities using equation 1. Figure 8 shows the amplitude of delay spectrum from *off-zenith* and *zenith* pointings. Notice the qualitative agreement of amplitude and structure with those obtained from data shown in Figure 4. The Galactic center and the Galactic plane

visible in the *off-zenith* pointing make it appear brighter in the *foreground wedge*.

Figure 8. Simulated delay spectrum amplitudes $|V_\eta(\vec{k}_\perp, \eta)|$ (in units of Jy Hz) for *off-zenith* (top) and *zenith* (bottom) pointings. White lines mark the boundaries of *foreground wedge* determined by horizon delay limit and antenna spacing. The axes and color scale are identical to those in Figure 4. The features resemble those obtained with MWA data shown in Figure 4. The Galactic center and Galactic plane prominently visible in the *off-zenith* pointing makes the emission in the *foreground wedge* brighter relative to that in the *zenith* pointing.

In order to make a quantitative comparison of delay spectra obtained with MWA data and our simulations, we consider the uncertainty in the assumed spectral index of our foreground model. Our foreground models are derived from other higher frequency catalogs and sky maps. The inherent spread in spectral index increases the uncertainty while predicting fluxes at the observed frequency. Using simple error propagation, the fractional error in the delay spectrum caused by the spread in spectral index is $\sim \ln(f_{\text{orig}}/f) \Delta \alpha_{\text{sp}}$, where, f_{orig} is the original frequency at which the catalog or map was created, $f = 185$ MHz is the observed frequency, and $\Delta \alpha_{\text{sp}}$ is the spread (HWHM) in spectral index. From Mauch et al. (2003), we assume $\Delta \alpha_{\text{sp}} \approx 0.35$ for compact objects from NVSS and SUMSS catalogs. Although the model of de Oliveira-Costa et al. (2008) yields a spectral index per direction on the sky, we assume similar uncertainties exist in spectral indices of our diffuse sky model as well, which is predominantly derived from the 408 MHz map of Haslam et al. (1982). Thus, fractional errors in delay spectrum from compact foreground objects and diffuse emission are $\sim 70\%$ and $\sim 30\%$ respectively.

In addition to intrinsic model uncertainty, delay spectra from simulations and data each have fluctuations due to thermal noise in delay spectrum with rms $\sim 1.4 \times 10^7$ Jy Hz. We estimate the ratio of delay spectra from data and simulations as, $\rho = |V_\eta^{\text{D}}(\vec{k}_\perp, \eta)| / |V_\eta^{\text{S}}(\vec{k}_\perp, \eta)|$, where superscripts D and S denote data and simulation respectively.

Figure 9 shows normalized histograms of the distribution of $\log_{10} \rho$ for the *off-zenith* (top panel) and *zenith* (bottom panel) pointings respectively inside the *foreground wedge*. The median absolute deviation from these distributions correspond to $\sim 90\%$ fractional difference between data and modeling on average in either case. This is in line with aforementioned uncertainty in foreground models and thermal noise fluctuations in measurements. Currently we are significantly limited by unavailability of all-sky foreground models at the observed frequency of 185 MHz.

Figure 9. Normalized histograms of logarithm of ratios of observed to simulated visibilities restricted to the *foreground wedge* – i.e., within the white lines of Figure 8 – for the *off-zenith* (top) and *zenith* (bottom) pointings. Median absolute deviation of $\log_{10} \rho$ is ~ 0.28 in both cases. A value of zero indicates when the ratio $\rho = 1$.

These uncertainties are presented only to confirm the qualitative agreement already seen between Figures 4 and 8 and are not intended to serve as a comprehensive estimate of all uncertainties involved. However, since we have not accounted for numerous other uncertainties, especially in the data, such as uncertainties in the antenna power-pattern, calibration, interference, and wide field imaging effects, our estimates of uncertainty are conservative. Accounting for such uncertainties will only improve our confidence level in this comparison. Our primary objective is to explore in detail the foreground signatures embedded in the *foreground wedge*.

5. RESULTS

Having established that the simulation matches the data to the level of expected uncertainties, we proceed to examine in further detail the key signatures seen in simulated delay spectra. A number of factors are responsible for the characteristics noted in the delay spectra obtained from data and through simulations. We address these factors below:

- *Sky Model:* Our model of the sky consists of bright compact objects and diffuse emission on diverse spatial scales as shown in Figures 6 and 7. It also consists of localized regions of strong emission such as the Galactic plane and Galactic center. The resulting sky emission is anisotropic. In fact, the patch of sky for MWA observations is chosen from regions of low foreground emission.
- *Baseline Orientation:* Since the spatial structure of our foreground model is not expected to be isotropic, we divide our antenna spacings by their orientation, θ_b . We use the following bins: $-67.5 \leq \theta_b < -22.5$, $-22.5 \leq \theta_b < 22.5$, $22.5 \leq \theta_b < 67.5$, and $67.5 \leq \theta_b < 112.5$. The bin centers are oriented towards South-East, East, North-East, and North respectively. Since delays depend on θ_b , binning by θ_b allows us to match delay spectrum features to different sky directions.
- *Tile Pointing and Power-Pattern:* Since the MWA tiles are steered electronically, the power-pattern of the tile changes in any observing mode that tracks the object. The pointing system is capable of steering to points on a regular $\sim 7^\circ$ grid. During observations we allow the sky to drift across the nearest available pointing, shifting between grid points as necessary. In our study, we take into account the effect of changing tile power-pattern on delay spectrum (Figure 5). The LST of our data ranges from ~ 21 hours through ~ 2 hours, and for our analysis we chose *off-zenith* and *zenith* pointings shown in Figure 3.
- *Instrumental Passband:* The instrumental passband characteristics have a direct effect on the delay transform owing to the Fourier relationship between the two. Due to excision of aliased edge channels repeated in each coarse channel of our passband, we observed repeated patterns of the *foreground wedge* in the delay spectra. As already mentioned earlier, we have used a deconvolution algorithm (*CLEAN*) to rid the delay spectra of band shape effects. Since this paper focuses on studying the effects of foreground on the delay spectra, we do not pursue the characterization of artifacts from the band shape and imperfections in *CLEAN* deconvolution.

It may be noted that numerous features overlap at varying levels of significance depending on combinations of parameters. We assign the features to their predominant causes. Secondly, we have used noiseless cases to clearly illustrate the observed foreground signatures. With the addition of noise in the visibilities which is subject to observing time, some of the weaker features may not be as prominently visible. Since the foreground signatures are far too numerous and they reside in a vast volume of parameter space such as antenna spacing length and orientation, power-pattern, patch of sky under observation, and instrumental configuration, we highlight only some examples of the most notable features observed in the delay spectra of foreground emission.

5.1. Diffuse Foreground Signatures

Figure 10 shows the amplitude of delay spectrum, $|V_\eta(\vec{\kappa}, \eta)|$, simulated with only the diffuse foreground model, omitting compact sources. The top and bottom panels correspond to *off-zenith* and *zenith* pointings respectively.

Figure 10. Simulated delay spectrum amplitudes $|V_\eta(\vec{\kappa}, \eta)|$ (in units of Jy Hz) for *off-zenith* (top) and *zenith* (bottom) pointings for the diffuse foreground model without any thermal noise. White lines mark the boundaries of *foreground wedge* determined by the horizon delay limit and antenna spacing. The axes and color scale are identical to those in Figures 4 and 8. In the *zenith* pointing, delay spectrum from diffuse emission has a *two-pronged fork*-shaped structure and is present even at wide antenna spacings.

Here we examine in detail some examples of interesting features observed with the diffuse foreground model.

5.1.1. Galactic Center on Eastward Antenna Spacings

The most prominent signature seen in the *off-zenith* pointing (top panel of Figure 10) is due to the bright Galactic center situated on the western horizon co-located with one of the bright secondary lobes of the power-pattern. It appears as a bright branch in the delay spectrum near the negative delay horizon delay limit. This feature is strongest at short antenna spacings and fades with increase in antenna spacing. This Galactic center signature is absent in the *zenith* pointing (bottom panel) because the Galactic center has already set over the horizon.

5.1.2. Diffuse Emission Delay Spectra

Figure 10 also demonstrates diffuse emission from within the primary field of view manifests in the *off-zenith* pointing as a branch at the top of the wedge, and at zero delay in the *zenith* pointing. The former is seen at positive delays because the primary lobe of the power-pattern is centered eastward of zenith, whereas in the latter it is centered at zenith. As we see from Equation 1, each baseline measures a single spatial mode on the

sky with an angular size scale inversely proportional to length of the baseline projected in the direction of emission. Thus, in the *zenith* pointing, the signature of the smooth sky model, the horizontal line at zero delay, fades away on antenna spacings $|\vec{\kappa}| \gtrsim 125$ m because the sky model is devoid of spatial structures on scales $\lesssim 0.75^\circ$. In the *off-zenith* pointing, we see power out to much longer baselines which is described below.

5.1.3. Diffuse Emission on Wide Antenna Spacings

A very interesting signature of diffuse emission is revealed at regions near the positive horizon delay limit in the *off-zenith* pointing and at both positive and negative horizon delay limits in the *zenith* pointing even on wide antenna spacings ($125 \text{ m} \lesssim |\vec{\kappa}| \leq 200 \text{ m}$). This is contrary to expectations because longer baselines are not expected to be sensitive to diffuse emission. In the wide-field observations of the MWA, long baselines appear shortened due to projection effects for off-axis emission, especially towards the horizon. This effect is evident at all LSTs in our simulations and it naturally holds for short baselines, as well. Thus, diffuse emission from far off-axis directions manifests as an edge-heavy *two-pronged fork* across all baselines. It decreases in strength with increasing baseline length as expected but is present in all baseline orientations.

5.2. Compact Foreground Signatures

Figure 11 shows the delay spectrum of compact foreground sky model (see Figure 7) for *off-zenith* and *zenith* pointings in the top and bottom panels respectively.

Figure 11. Simulated delay spectrum amplitudes $|V_\eta(\vec{\kappa}, \eta)|$ (in units of Jy Hz) for *off-zenith* (top) and *zenith* (bottom) pointings for the compact objects foreground model without any thermal noise. White lines mark the boundaries of *foreground wedge* determined by the horizon delay limit and antenna spacing. The axes and logarithmic color scale are identical to those in Figures 4, 8 and 10. Emission from compact objects gives rise to centrally concentrated features and stays flat across antenna spacings in the *foreground wedge*.

In contrast to delay spectrum of diffuse emission, compact emission manifests as a center-heavy structure in the delay spectrum with either pointing. This contributes to the *pitchfork* feature which will be discussed in detail in §5.3. Below we summarize some specific notable features obtained with our compact objects foreground model.

The amplitude response of an interferometer to a compact object is, to first order, flat with respect to baseline length. Since the main lobe of the power-pattern in the *off-zenith* pointing is centered eastward of zenith, the bulk of the compact foreground emission is seen in a branch with positive delay corresponding to the position of the primary lobe of the power-pattern. In the *zenith* pointing, compact emission from the same patch of sky is seen as a bright horizontal arm at zero delay since the primary lobe of the power-pattern is centered at zenith.

Foreground emission in zero delay and negative delay regions in the *off-zenith* pointing is caused by compact objects co-located with secondary lobes of the power-pattern. On the other hand, compact objects co-located with secondary lobes of power-pattern in the *zenith* pointing are revealed as faint but distinct branches at positive and negative delays depending on the orientation of antenna spacing and direction of emission on the sky.

5.3. The "Pitchfork"

Delay spectra from the all-sky foreground model in our study display a composite feature set drawn from the features of compact and diffuse foreground models. Here we compare the relative strengths of emission from different spatial scales in our all-sky composite foreground model.

When not dominated by the bright emission from the Galactic center, which happens only for certain pointings at certain times, the delay spectrum of the combined foreground model is dominated, in somewhat equal measure, by diffuse and compact emission. This is illustrated by a more detailed examination of the *zenith* pointing in our study.

Figure 12 shows delay spectra of three antenna pairs of different antenna spacings oriented northward during the *zenith* pointing; each is a different vertical slice of the two dimensional delay spectrum plots shown in Figures 4, 8, 10 and 11. The diffuse, compact, and composite components are shown as dotted, dashed, and solid lines respectively. The horizon delay limits are shown as a pair of vertical dot-dashed lines. The gray shaded area denotes the envelope of expected uncertainty in the delay spectrum. Uncertainty in emission in the *foreground* wedge (between the horizon delay limits) is dominated by the $\gtrsim 70\%$ error owing to uncertainties in predicting the spectral index of compact foreground objects, while thermal noise fluctuations dominate outside.

The zero-delay peak (corresponding to the main lobe in the power-pattern) with a value of $\sim 10^8$ – 10^9 Jy Hz, independent of antenna spacing, is predominantly determined by compact foreground objects. The corresponding peak at zero-delay from diffuse foreground model is at least 10 times fainter and decreases drastically with increase in antenna spacing. This is the response expected from different antenna spacings towards compact and diffuse foreground objects.

Near the horizon delay limits at shorter antenna spac-

Figure 12. Simulated delay spectrum amplitudes $|V_\eta(\bar{\mathbf{x}}, \eta)|$ for three chosen antenna spacings of length: ~ 84 m (*top*), ~ 105 m (*middle*), and ~ 170 m (*bottom*). The antenna spacing is specified in each panel along East, North and Upward directions. The dotted, dashed and solid lines denote contributions from diffuse emission, compact objects and composite foreground model respectively. Vertical dot-dashed lines mark the horizon delay limits. The shaded region denotes the envelope of uncertainty around the composite model delay spectrum. This uncertainty is dictated by uncertainties in spectral indices of foreground models inside the delay horizon delay limits. Outside the horizon delay limits, it is predominantly due to thermal noise fluctuations. Compact objects dominate the central regions of delay spectrum while both components, especially diffuse emission on short antenna spacings, dominate near the horizon delay limits, giving rise to a *pitchfork*-shaped structure.

ing, diffuse emission is brighter than that from compact objects. Here, diffuse emission does not decrease as rapidly with increasing antenna spacing as was seen at zero-delay. In fact, even on widely spaced antennas, diffuse emission in the delay spectrum near the horizon delay limits exceeds that in the main lobe by more than two orders of magnitude. We attribute this to apparent shortening of antenna spacings projected in the direction of diffuse emission entering far from the primary field of view. This demonstrates the edge-heavy *two-pronged fork* feature discussed in §5.1.3.

Full simulations show the combination of center-heavy features on all antenna spacings from compact objects and edge-heavy features from both components especially diffuse emission even on wide antenna spacings. This results in a characteristic *pitchfork* structure imprinted in the *foreground* wedge and should be evident in observations.

All these observations are consistent with those from

Figures 10 and 11. The observability of the *pitchfork* signature predicted in this paper depends on relative levels of uncertainty in the foreground model and fluctuations from thermal noise. In our simulations, since thermal noise in these very short duration snapshots is $\gtrsim 10^7$ Jy Hz, and features near the horizon delay limits are $\sim 10^7$ Jy Hz, the *pitchfork* feature is not expected to be detected in a noisy scenario although this feature is marginally visible in the *zenith* pointing of observed data (see Figure 4). We attribute this to differences between our foreground model and the actual sky. Deeper observations should reveal the feature clearly.

We also note that increasing the antenna spacing results in progressively improving the resolution along delay axis by increasing the number of delay bins inside the *foreground wedge*. This improves the localization of foreground objects whose signatures are imprinted in the delay spectrum. For instance, there is an increase in the number of secondary peaks in the delay spectrum between zero-delay and horizon delay limits as antenna spacing increases from ~ 84 m to ~ 170 m. In this case, these correspond to secondary lobes of the power-pattern that lie between the primary lobe and the horizon along the local meridian. At short antenna spacings, due to relatively lower resolution along delay axis inside the *foreground wedge* and a consequent loss of localization of foreground emission, these secondary peaks blend in with other major peaks and are not distinctly visible. These findings are consistent with the discussion in §5.2.

In summary, the brightest signature ($\gtrsim 10^{10}$ Jy Hz) is that of the Galactic center in the *off-zenith* pointing co-located at a westward secondary lobe with a significantly high gain. The next brightest signature ($\sim 10^8$ – 10^9 Jy Hz) is caused by compact emission appearing to be concentrated in the inner regions of the *foreground wedge* (near zero delays) rather than towards the boundaries. Diffuse emission co-located at the primary lobe of the power-pattern is fainter by approximately an order of magnitude relative to compact emission from the same region for a ~ 84 m antenna spacing. But unlike the latter, diffuse emission decreases rapidly by over two orders of magnitude as antenna spacing is widened to ~ 170 m. However, diffuse emission is significantly high near horizon delay limits compared to that in the primary lobe of the power-pattern as antenna spacing is widened. This leads to edge-heavy features in the delay spectrum. Complemented by the center-heavy compact foreground features, we predict the presence of a *three-pronged pitchfork*-shaped signature in the delay spectrum of foreground sky. We identify evidence for presence of this signature in actual MWA data, although deeper observations are needed to more clearly reveal the effect.

6. APPLICATIONS

While the *foreground wedge* is a region of high foreground contamination, of particular interest to the EoR community is foreground contamination near horizon delay limits. These regions are believed to be responsible for significant spillover into the relatively clean *EoR window* due to spectral response of the instrument and foregrounds.

The Galactic center in the *off-zenith* pointing is one such example already available in our study. Figure 13a

shows the sky model (*top*: compact objects, *bottom*: diffuse sky model) in this pointing. The Galactic center is the most dominant source of foreground contamination from the diffuse sky model and is co-located with a bright secondary lobe of the power pattern. Figure 13b shows the sky mapped to delays registered by the baseline vectors, of length 100 m for instance, oriented northward (top panel) and eastward (bottom panel). Since the Galactic center is located in the western sky, this figure demonstrates that it is observed at negative delay on a baseline vector oriented eastward and at zero delay on a baseline vector oriented northward. Figure 13c shows the delay spectra on baselines oriented northward ($67.5^\circ \leq \theta_b < 112.5^\circ$) at the top and eastward ($-22.5^\circ \leq \theta_b < 22.5^\circ$) at the bottom. The Galactic center manifests itself most distinctly near the negative horizon delay limit on short eastward baselines in the delay spectrum (bottom panel of Figure 13c). Consequently, the spillover caused by the instrument’s transfer function from the *foreground wedge* into the *EoR window* is most severe in eastward baselines relative to northward baselines evident by the bright vertical stripes of foreground contamination.

The delay spectrum, $V_\eta(\vec{x}, \eta)$, not only carries information on spatial scales of foreground emission but also offers a unique advantage of viewing the sky through a combination of antenna spacing vector and the delay axis. With a foreground model known *a priori* in which structures and locations of very bright foreground objects such as the Galactic center or AGN are available, we can predict their response across antenna spacings as a function of observing parameters such as LST, power-pattern, etc. This allows us to programmatically screen data for antenna spacings that are severely contaminated by foregrounds near the horizon delay limits in the delay spectrum. These can be weighted appropriately during data analysis. We demonstrate such a screening technique, whereby we use the bright object’s location and structure to discard antenna spacings of certain lengths and orientations to mitigate foreground contamination in the *EoR window*.

In our example, we discard eastward antenna spacings ($-22.5^\circ \leq \theta_b < 22.5^\circ$) of lengths $|\vec{x}| < 40$ m. Figure 14 shows the delay spectra obtained with all antenna spacings (top panel) and after applying our screening technique (bottom panel) on the *off-zenith* observation. Notice the remarkable reduction – by about an order of magnitude – in foreground contamination in this region after application of our screening technique.

We further demonstrate this screening technique can be customized when it is necessary to optimize between foreground mitigation and loss of sensitivity from discarding data. Figure 15 shows how the typical foreground contamination in the *EoR window* depends on the orientations and lengths of discarded antenna spacings. We choose antenna spacings oriented eastward to varying degrees of directedness, i.e., $-7.5^\circ \leq \theta_b < 7.5^\circ$ (solid circles), $-15^\circ \leq \theta_b < 15^\circ$ (solid squares), and $-22.5^\circ \leq \theta_b < 22.5^\circ$ (solid stars). Among antenna spacings that satisfy these criteria, we discard data from those whose lengths are shorter than $|\vec{x}|_{\max}$ (x -axis) and show foreground contamination estimated in the *EoR window* from all remaining antenna spacings. Foreground contamination estimated from only northward (dashed line)

Figure 13. (a): Sky model showing compact objects (*top*) and diffuse emission (*bottom*). Contours of power pattern are overlaid whose levels are identical to those in Figures 6 and 7. The Galactic center is very prominent in diffuse emission in the western sky and is co-located with a bright secondary lobe of the power pattern. (b): Sky hemisphere mapped to delays observed on antenna spacings with northward (*top*) and eastward (*bottom*) orientations. Color scale shown is for a 100 m antenna spacing. Delays vary linearly with antenna spacing length. The bright Galactic center in the western sky is recorded at zero delays in northward antenna spacings and close to negative horizon delay limit on eastward antenna spacings. (c): Simulated delay spectra $|V_\eta(\vec{x}, \eta)|$ on antenna spacings oriented northward (*top*) and eastward (*bottom*). The bright Galactic center is prominently visible close to negative horizon delay limit on eastward antenna spacings. These are also the most severely contaminated by foreground spillover. The northward antenna spacings, on the other hand, are the least contaminated.

Figure 14. Simulated delay spectra amplitudes $|V_\eta(\vec{x}, \eta)|$ for the *off-zenith* pointing with all antenna spacings included (*top*) and with short eastward antenna spacings discarded (*bottom*). Discarded antenna spacings have lengths $|\vec{x}| < 40$ m and orientations $-22.5^\circ \leq \theta_b < 22.5^\circ$. The spillover from the bright Galactic center near the negative horizon delay limit from the *foreground wedge* prominent when all antenna spacings are used is reduced by an order of magnitude when short eastward antenna spacings are discarded.

and eastward (dot-dashed line) antenna spacings represent the lower and upper limits respectively, and are shown for reference. It is seen that foreground contamination can be mitigated by a factor between ~ 1.5 ($|\theta_b| \leq 7.5^\circ$) and ~ 10 ($|\theta_b| \leq 22.5^\circ$). It is notable that short antenna spacings play maximum role in determin-

ing foreground contamination. For instance, among antenna spacings with orientations $|\theta_b| \leq 22.5^\circ$, discarding those with lengths $|\vec{x}| > 40$ m has no effect on foreground contamination and would only lead to loss of sensitivity. On the other hand, a bright compact object at the same location will give rise to foreground contamination even on longer antenna spacings. Such cases will necessitate discarding more or all of the eastward oriented antenna spacings.

In principle, instead of discarding selected antenna spacings altogether, we could down-weight them based on an optimal scheme. This technique provides a very simple and yet effective tool in adding a layer of control to mitigate effects of foreground contamination in EoR data analysis.

7. SUMMARY

Our primary motivation in this work is to understand how the various bright foregrounds will manifest in three dimensional power spectrum of H I from 21 cm reionization observations. In the units presented here, the dynamic range between bright foregrounds and the 21 cm signal is expected to be $\sim 10^8$; a detailed understanding of how foregrounds can corrupt the 21 cm power spectrum is therefore essential. This analysis extends previous work by simulating the entire sky rather than just the central field of view and by providing a comparison with early observations from the MWA. By making use of the delay spectrum technique to estimate power spectrum, we are able to observe the effects of foregrounds while avoiding entanglements with more complex power spectrum estimators.

Simulating in all important respects the response of the MWA to an all-sky foreground model that consists of diffuse Galactic emission from de Oliveira-Costa et al. (2008) and bright compact objects from the NVSS and SUMSS catalogs, we confirm that the modeled delay spectra is in agreement with data obtained with the

Figure 15. Foreground contamination in *EoR window* for the *off-zenith* pointing as a function of orientation and length of discarded antenna spacings. Antenna spacings oriented eastward with varying degrees of directedness are considered: $-7.5^\circ \leq \theta_b < 7.5^\circ$ (solid circles), $-15^\circ \leq \theta_b < 15^\circ$ (solid squares), and $-22.5^\circ \leq \theta_b < 22.5^\circ$ (solid stars). Among antenna spacings that satisfy the above criteria, ones with lengths $\leq |\bar{x}|_{\max}$ (x -axis) are discarded. Lower (dashed line) and upper (dot-dashed) limits on foreground contamination are derived from northward ($67.5^\circ \leq \theta_b < 112.5^\circ$) and eastward ($|\theta_b| \leq 22.5^\circ$) antenna spacings respectively. Foreground contamination in the *EoR window* reduces by factor ~ 1.5 ($|\theta_b| \leq 7.5^\circ$) to ~ 10 ($|\theta_b| \leq 22.5^\circ$). Short baselines have maximum effect on foreground contamination. For instance, discarding antenna spacings oriented $|\theta_b| \leq 22.5^\circ$ with lengths $|\bar{x}| > 40$ m has no effect in reducing foreground contamination.

MWA, to the extent allowed by levels of uncertainty known in the foreground models and thermal noise fluctuations in measurements.

Looking deeper at our simulations, below the level of the instrumental noise, we identify numerous signatures of different components of foreground emission seen in the delay spectra. We establish the relationship between these signatures and observing parameters such as antenna pointing and LST, instrument parameters such as antenna power-pattern and bandpass shape, and foreground parameters such as the nature of emission, spectral index, etc.

The bright Galactic center at the edge of the western horizon co-located with one of the far secondary lobes of MWA tile power-pattern is the brightest source of foreground contamination in the *off-zenith* pointing. It manifests itself near the negative horizon delay limit in the delay spectrum on antenna spacings oriented eastward.

As expected, diffuse emission in the primary beam of the antenna power-pattern is prominent on shorter antenna spacings. However, the most interesting result is its footprint on wide antenna spacings near the horizon delay limits, an edge-heavy *two-pronged fork-shaped* signature. This is due to apparent shortening of wide antenna spacings in the direction of foreground emission far off-axis thereby retaining their response to extended emission. On the other hand, compact fore-

ground objects predominantly map onto central regions of the *foreground wedge*. Features arising from compact objects co-located with primary and secondary lobes of antenna power-pattern have been identified. In general, delay spectrum signatures of compact objects are center-heavy, in clear contrast to those from diffuse emission. A composite all-sky foreground model consisting of diffuse and compact foregrounds combines the characteristic individual shapes into a *pitchfork-shaped* structure in the *foreground wedge*. This will be distinctly visible when the thermal noise floor is sufficiently lowered, as longer observations are processed through the MWA analysis pipeline.

In conclusion, we find that inclusion of objects, both diffuse and compact, all the way to the horizon is essential to explaining the observed power spectrum. We also provide a simple and effective tool based on the delay spectrum technique to mitigate foreground contamination by an order of magnitude in EoR data analysis. It is possible to discard or down-weight antenna pairs most affected by foreground contamination as a function of antenna spacing vector and time of observation.

DCJ is supported by an NSF Astronomy and Astrophysics Postdoctoral Fellowship under award AST-1401708. This work makes use of the Murchison Radio-astronomy Observatory, operated by CSIRO. We acknowledge the Wajarri Yamatji people as the traditional owners of the Observatory site. Support for the MWA comes from the NSF (awards: AST-0457585, PHY-0835713, CAREER-0847753, and AST-0908884), the Australian Research Council (LIEF grants LE0775621 and LE0882938), the U.S. Air Force Office of Scientific Research (grant FA9550-0510247), and the Centre for All-sky Astrophysics (an Australian Research Council Centre of Excellence funded by grant CE110001020). Support is also provided by the Smithsonian Astrophysical Observatory, the MIT School of Science, the Raman Research Institute, the Australian National University, and the Victoria University of Wellington (via grant MED-E1799 from the New Zealand Ministry of Economic Development and an IBM Shared University Research Grant). The Australian Federal government provides additional support via the Commonwealth Scientific and Industrial Research Organisation (CSIRO), National Collaborative Research Infrastructure Strategy, Education Investment Fund, and the Australia India Strategic Research Fund, and Astronomy Australia Limited, under contract to Curtin University. We acknowledge the iVEC Petabyte Data Store, the Initiative in Innovative Computing and the CUDA Center for Excellence sponsored by NVIDIA at Harvard University, and the International Centre for Radio Astronomy Research (ICRAR), a Joint Venture of Curtin University and The University of Western Australia, funded by the Western Australian State government.
